The  $1/\emptyset$  coding on ATN when sent concurrent with multiline messages has been added to this revision for interpretive convenience.

#### NOTES

- (1) D1-D8 specify the device dependent data bits.
- (2) E1-E8 specify the device dependent code used to indicate the EOS message.
- (3) L1-L5 specify the device dependent bits of the device's listen address.
- (4) T1-T5 specify the device dependent bits of the device's talk address.
- (5) S1-S5 specify the device dependent bits of the device's secondary address.
  - (6) S specifies the sense of the PPR.

| S | Response |
|---|----------|
| Ø | 0        |
| 1 | 1        |

P1-P3 specify the PPR message to be sent when a parallel poll is executed.

| P3 | P2 | Pl | PPR Message |
|----|----|----|-------------|
| Ø  | θ  | Ø  | PPR1        |
| 10 |    | 8  |             |
|    |    |    |             |
| 9  |    |    |             |
| 1  | 1  | 1  | PPR8        |

- (7) D1-D4 specify don't-care bits that shall not be decoded by the receiving device. It is recommended that all zeroes be sent.
- (8) S1-S6, S8 specify the device dependent status. (DIO7 is used for the RQS message.)
- (9) The source of the message on the ATN line is always the C function, whereas the messages on the DIO and EOI lines are enabled by the T function.
- (10) The source of the messages on the ATN and EOI lines is always the C function, whereas the source of the messages on the DIO lines is always the PP function.
- (11) This code is provided for system use, see 6.3.

# INTRODUCTION

Microprocessor-based system designs are a costeffective solution to a wide variety of problems. When a system designer is presented with the task of selecting a microprocessor for a design, the capabilities of the microprocessor should not be the only consideration. The microprocessor should be an element of a compatible family of devices. The MCS-80 component family is a group of compatible devices which have been designed to directly address and solve the problems of microprocessor-based system design. One member of the MCS-80 component family is Intel's 8255A programmable peripheral interface chip. This device replaces a significant percentage of the logic required to support a variety of byte oriented Input/ Output interfaces. Through the use of the 8255A, the I/O interface design task is significantly simplified, the design flexibility is increased, and the number of components required is reduced.

This application note presents detailed design examples from both the hardware and software points of view. Since the 8255A is an extremely flexible device, it is impossible to list all of the applications and configurations of the device. A number of designs are presented which may be modified to fulfill specific user interface requirements.

Detailed design examples are discussed within the context of the 8080 system shown in Figure 1. The basic 8080 system is composed of the CPU module, memory module, and the I/O module. CPU module and memory module design are discussed

within other Intel publications. This application note deals exclusively with I/O module design.

It is assumed that the reader is familiar with the MCS-80 User's Manual and/or the MCS-85 User's Manual, particularly the 8255A device description.

# **OVERVIEW OF THE 8255A**

The 8255A block diagram shown in Figure 2 has been divided into three sections: 8080 CPU Module Interface, Peripheral Interface, and the Internal Logic.

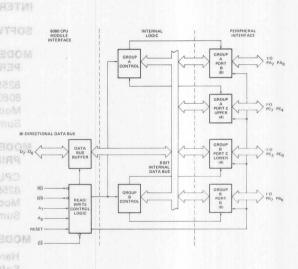

Figure 2. 8255A Block Diagram

# DATA BUS (8 LINES) CONTROL BUS (6 LINES) ADDRESS BUS (16 LINES)

# 8080 CPU MODULE INTERFACE

The 8255A is a compatible member of the MCS-80 component family and, therefore, may be directly interfaced to the 8080. Figure 3 displays one method of interconnecting the 8255A and an 8080 CPU module. The 8080 CPU module consists of the 8080A CPU, the 8224 Clock Generator, and the 8228 System Controller. The system shown in Figure 3 utilizes a linear select scheme which dedicates an address line as an exclusive enable (chip select) for each specific I/O device. The chip select signal is used to enable communication between the selected 8255A and the 8080 CPU. I/O Ports A, B, C, or the Control Word Register are selected by the two port select signals (A1, A0). These signals (A<sub>1</sub> and A<sub>0</sub>) are driven by the least significant bits of the address bus. The I/O port select characters required by this configuration are shown in Figure 4.

When a system utilizing the linear select scheme is implemented, a maximum of six I/O devices may be selected. If more than six I/O devices must be addressed, the six device select bits must be encoded to generate a maximum of 64 device select lines. Note that when large systems are implemented, bus loading considerations may require that bus drivers be included in the CPU module. The MCS-80 component family contains parts which are designed to perform this function (8216, 8226).

The 8255A I/O read (\$\overline{RD}\$) and I/O write (\$\overline{WR}\$) signals may be directly driven by the 8228. This results in an isolated I/O architecture where 8080 Input/Output instructions are used to reference an independent I/O address space. An alternate approach is memory mapped I/O. This architecture treats an area of memory as the I/O address space. The memory mapped I/O architecture utilizes 8080 memory reference instructions to access the I/O address space. Interfacing with the 8080 is outlined in Chapter 3 of the "8080 Microcomputer User's Manual".

The most important feature of the 8255A to 8080 CPU Module Interface is that for small system designs the 8255A may be interfaced directly to

the standard MCS-80 component family with no external logic. Minimum external logic is required in large system designs.

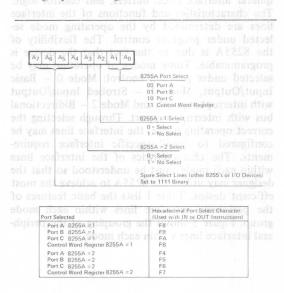

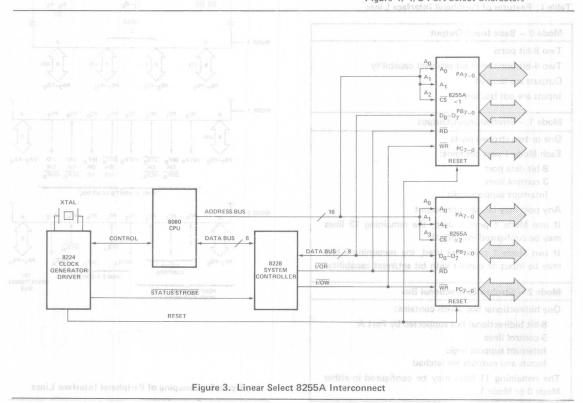

Figure 4. I/O Port Select Characters

ipheral interface lines, buffers, and control logic. The characteristics and functions of the interface lines are determined by the operating mode selected under program control. The flexibility of the 8255A is due to the fact that the device is programmable. Three modes of operation may be selected under program control: Mode 0 - Basic Input/Output, Mode 1 - Strobed Input/Output with interrupt support, and Mode 2 – Bidirectional bus with interrupt support. Through selecting the correct operating mode, the interface lines may be configured to fulfill specific interface requirements. The characteristics of the interface lines within each mode must be understood so that the designer may utilize the 8255A to achieve the most efficient design. Table I lists the basic features of the peripheral interface lines within each mode group. Figure 5 shows the grouping of the peripheral interface lines within each mode.

Table I. Features of Peripheral Interface Lines

# Mode 0 - Basic Input/Output

Two 8-bit ports

Two 4-bit ports with bit set/reset capability

Outputs are latched

Inputs are not latched

# Mode 1 - Strobed Input/Output

One or two strobed ports

Each Mode 1 port contains:

8-bit data port

3 control lines

Interrupt support logic

Any port may be input or output

If one Mode 1 port is used, the remaining 13 lines may be configured in Mode 0.

If two Mode 1 ports are used, the remaining 2 bits may be input or output with bit set/reset capability.

# Mode 2 - Strobed Bidirectional Bus

One bidirectional bus which contains:

8-bit bidirectional bus supported by Port A

5 control lines

Interrupt support logic

Inputs and outputs are latched

The remaining 11 lines may be configured in either Mode 0 or Mode 1.

Through the use of this teature, device strobes may be easily generated by software without utilizing external logic. The Mode 1 and Mode 2 configurations use a number of the Port C lines for interrupt control lines. Thus, the 8255A contains a large portion of the logic required to implement an interrupt driven I/O interface. This feature simplifies interrupt driven hardware design and saves a significant amount of the external logic that is normally required when less powerful I/O chips are used. In fact, the design examples contained in this application note describe how interrupt driven interfaces may be designed such that the only interrupt control logic required is that contained in the 8255A.

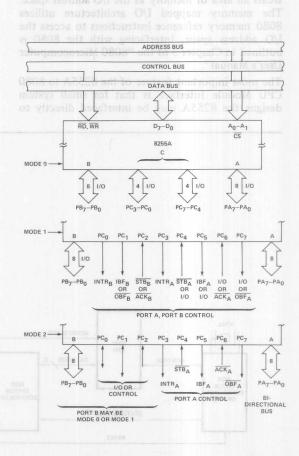

Figure 5. Grouping of Peripheral Interface Lines

# Control word (see Front Sac Signal Language)

The internal logic section manages the transfer of data and control information on the internal data bus (refer to Figure 2). If the port select lines (A1 and A<sub>0</sub>) specify Ports A, B, or C, the operation is an I/O port data transfer. The internal logic will select the specified I/O port and perform the data transfer between the I/O port and the CPU interface. As was previously mentioned, both the functional configuration of each port and bit set/reset on Port C are controlled by the system's software. When the control word register is selected, the internal logic performs the operation described by the control word. The control word contains an opcode field which defines which of the two functions are to be performed (mode definition or bit set/reset).

# Mode Definition JORTHOD 1- AMESS:

When the opcode field (Bit 7) of the control word is equal to a one, the control word is interpreted by the 8255A as a mode definition control word. The mode definition control word (shown in Figure 6) is used to specify the configuration of the

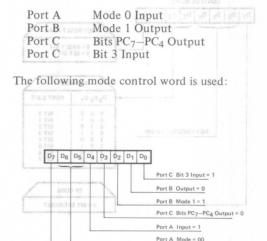

control word into the A register Since it is known that the set bit cor-D7 D6 D5 D4 D3 D2 D1 D0 A 9 00 A 9 00 A GROUP B PORT C (LOWER - PC3-PC0 TO ORESET BIT 3 1 = INPUT 1 0 = OUTPUT PORT B 1 = INPUT 0 = OUTPUT MODE SELECTION 0 = MODE 0 1 = MODE 1 his example demonstrates Example rforming a bit set/reset opera-B. Figure 6. Mode Definition Control Word

24 8255A peripheral interface lines. The system's software may specify the modes of Port A and Port B independently. Port C may be treated independently or divided into two portions as required by the Port A and Port B mode definitions.

Example #1: This example demonstrates how a mode control word is constructed and issued to an 8255A. The mode control word is passed to the device through the use of an output instruction that references an 8080 I/O port address. The value of the I/O port address is determined by the 8080 CPU interface implemented. This example references the I/O port addresses realized by the simple 8080 to 8255A interface shown in Figure 3.

If an 8255A is to be configured through the use of the mode control word interface as:

Opcode Mode Set = 1

The assembly language program is:

Mode Control Word = 10010101 Binary

Example #2: This example demonstrates how a Port C bit set/reset control word is constructed and issued to an MCZ-SA The bit set/reset control word is set/reset control word is set/reset control word in the set of the se

# Bit Set/Reset and sectional interface from teaching ASSSA 45

When the opcode field (Bit 7) of the control word is equal to a zero, the control word is interpreted by the 8255A as a Port C bit set/reset command word (see Figure 7). Through the use of the bit set/reset command, any of the 8 bits on Port C may be independently set or reset. Note that control word bits 6-4 are not used. Bits 6-4 should be set to zero.

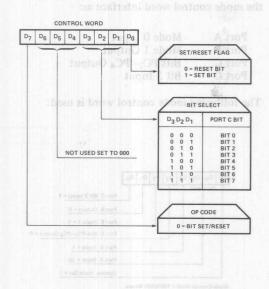

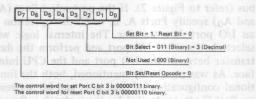

Figure 7. Bit Set/Reset Control Word

Example #2: This example demonstrates how a Port C bit set/reset control word is constructed and issued to an 8255A. The bit set/reset control word is passed to the device through the use of an output instruction that references an 8080 I/O port address. The value of the I/O port address is determined by the 8080 CPU interface implemented. This example references the I/O port addresses realized by the simple 8080 to 8255A interface shown in Figure 3.

Control word (see Figure 7).

The control word for reset Port C bit 3 is 00000110 binary.

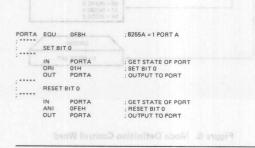

The assembly language program is:

NOTE: An MVI instruction is used to load the reset bit 3 control word into the A register. Since it is known that the set bit control word is already in the A register, a "DCR A" Instruction could be used to generate the correct control word and save one byte of code.

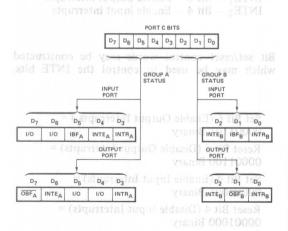

00000111 - 1 = 00000110 (RESET BIT 3 CONTROL WORD)

Example #3: This example demonstrates one simple method of performing a bit set/reset operation on Ports A and B. The state of any output port may be determined by reading the port. The assembly language program which may be used to set/reset Port A or B bits is:

# 

As previously mentioned, the 8255A Mode 1 and Mode 2 configurations support interrupt control logic. If a read of Port C is issued when the 8255A is configured in Mode 1, the software will receive the Mode 1 status word shown in Figure 8. The bits in the status word correspond to the state of the associated Port C lines (buffer full, interrupt request, etc.). The INTE bit shown in the status word corresponds to the interrupt enable flip-flop contained in the 8255A. This signal is not available externally. The structure of the Mode 1 status word varies as a function of the mode of the 8255A. Example #4 shows the status word which results from reading Port C from an 8255A which is configured with Port A Mode 1 input and Port B Mode 1 output.

The control words shown were constructed from the standard bit set/riset format shown in Fig.

Figure 8. Mode 1 Status Word

# Example #4 - MODE 1 STATUS WORD

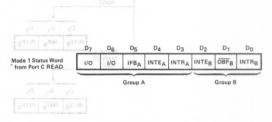

If an 8255A is to be configured through the use of the mode control word interface as:

Port A Mode 1 Input
Port B Mode 1 Output
Port C Bits 6 & 7 Output

The following mode control word is used:

The training and the state of the second and the state of the second and the seco

After the 8255A mode control word has been issued, a READ of Port C will obtain the following Mode 1 status word:

NOTE: The Port C I/O bits D<sub>7</sub> and D<sub>6</sub> should be modified through the use of the Port C bit set/reset command word. If a write to Port C is issued, the INTE<sub>A</sub> and INTE<sub>B</sub> bits may be inadvertently modified by the user. The IBF<sub>A</sub>, INTR<sub>A</sub>, OBF<sub>B</sub>, and INTR<sub>B</sub> bits will not be modified by either a write to Port C or a bit set/reset command. These four bits always reflect the state of the interrupt control logic.

Port A Mode 2 Bidirectional Bus
Port B Mode 1 Input
he following mose control word is used:

Note that the Mode 2 status word (shown in Figure 9) differs from the Mode 1 status word. The format of the status word data bits  $D_2$ – $D_0$  are defined by the specification of the Port B configuration. Example #5 shows the structure of the Mode 2 status word when the 8255A is configured with Port A Mode 2 (bidirectional bus) and Port B Mode 1 input.

The Mode 1 and Mode 2 status words reflect the state of the interrupt logic supported by the 8255A.

ples provide a more detailed explanation of the use of the Port C status word in the Mode 1 and Mode 2 configurations.

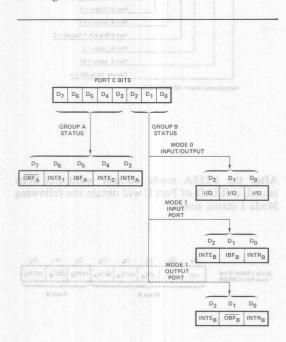

Figure 9. Mode 2 Status Word

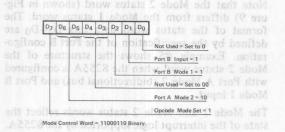

Example #5 – MODE 2 STATUS WORD

If the 8255A is to be configured as follows:

Port A Mode 2 Bidirectional Bus

Port B Mode 1 Input

The following mode control word is used:

Example #6 - MODE 2 INTERRUPT ENABLE/DISABLE

The Mode 2 status word shown in Figure 9 contains two interrupt enable bits:

INTE<sub>1</sub> - Bit 6 - Enable output interrupts INTE<sub>2</sub> - Bit 4 - Enable input interrupts

Bit set/reset control words may be constructed which may be used to control the INTE bits.

Set Bit 6 (Enable Output Interrupts ) = 00001101 Binary

Reset Bit 6 (Disable Output Interrupts) = 00001100 Binary

Set Bit 4 (Enable Input Interrupts) = 00001001 Binary

Reset Bit 4 (Disable Input Interrupts) = 00001000 Binary

The control words shown were constructed from the standard bit set/reset format shown in Figure 7.

The value of CWR used in the following program example corresponds to the 8080 configuration shown in Figure 3.

| EQU   | OFBH                | ; 8255A = 1 CONTROL WORD REGISTER                                                  |

always issue the correct mode control word after a reset of the device. Generally, an initialization routine is constructed which issues the correct mode control word, sets up the initial state of the control lines, and initializes any program internal data.

Many of the software requirements of the 8255A vary as a function of the mode selected. The simplest mode supported by the device is Mode 0 (Basic Input/Output). Generally, Mode 0 is used for simple status driven device interfaces (no interrupts). Figure 10 illustrates sample software that could be used to support such interfaces. Most devices support a BUSY or READY signal which is used to determine when the device is ready to input or output data and a DATA STROBE which is used to request data transfer (DATA STROBE may easily be generated with the Port C bit set/ reset feature). In the Mode 0 configuration, Ports A and B are used to input/output byte oriented data. Port C is used to input 8255A status, peripheral status and to drive peripheral control lines. When the Mode 1 and Mode 2 configurations are used, the software is generally required to support interrupts. Software routines written for an interrupt driven environment tend to be more complex than status driven routines. The added complexity is due to the fact that interrupt driven systems are constructed such that other software tasks are run while the I/O transaction is in progress. A software routine that controls a peripheral device is generally referred to as a device driver. One method of implementing an interrupt driven device driver is to partition the device driver into a "Command Processor" and an "Interrupt Service Routine". The command processor is the module that validates

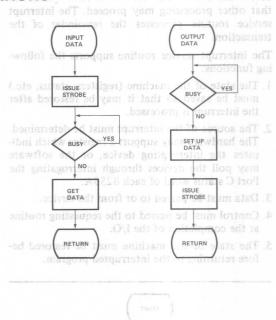

Figure 10. Sample Status Driven Software Flowchart

and initiates user program requests to the device driver. A common method of passing information between the various software programs is to have the requesting routine provide a device control block in memory. A sample device control block is shown in Table II.

Table II. Sample Device Control Block

| NAME                        | DESCRIPTION                                                                                                                     |
|-----------------------------|---------------------------------------------------------------------------------------------------------------------------------|
| Status                      | This 1-byte field is used to transmit the status of the I/O transaction (busy, complete, etc.).                                 |
| Opcode                      | This 1-byte field defines the type of I/O (READ, WRITE, etc.).                                                                  |
| Buffer Address              | This 2-byte field specifies the source/destination of the data block.                                                           |
| Character Count             | This 1-byte field is a count of the number of characters involved in the transaction.                                           |
| Character Transferred Count | This 1-byte count of the number of characters which were actually transferred.                                                  |
| Completion Address          | This 2-byte field is the address of the user supplied completion routine which will be called after the I/O has been performed. |

The command processor validates the transaction and initiates the operation described by the control block. Control is then returned to the requestor so that other processing may proceed. The interrupt service routine processes the remainder of the transaction.

The interrupt service routine supports the following functions:

- 1. The state of the machine (registers, status, etc.) must be saved so that it may be restored after the interrupt is processed.
- 2. The source of the interrupt must be determined. The hardware may support a register which indicates the interrupting device, or the software may poll the devices through interrogating the Port C status word of each 8255A.
- 3. Data must be passed to or from the device.
- 4. Control must be passed to the requesting routine at the completion of the I/O.
- 5. The state of the machine must be restored be-

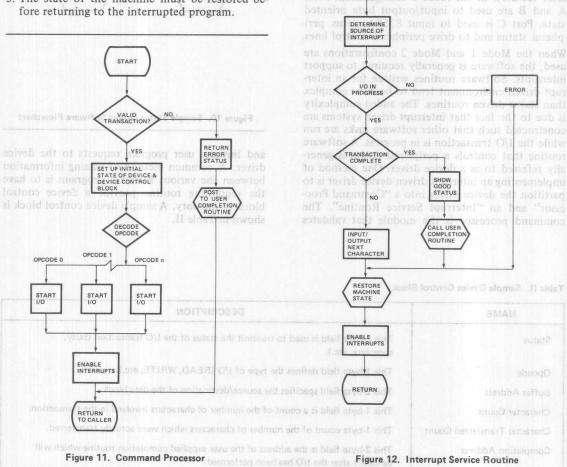

Figures 11 and 12 are simplified flowcharts of one of the many methods of implementing command processor and interrupt service routine modules. The rest of this application note presents specific application examples. All of the 8080 assembly language programs supplied with the application examples use the standard Intel 8080 assembly language mnemonics. The programs discussed use the program equate statement to specify all hard-

ware related data. Equate statements are used so that all references to an I/O port may be changed through a simple reassignment of the port address in the equate statement.

devices support a BUSY or READ THURRATHI WHICH IS

STATE

# MODE 0 – STATUS DRIVEN PERIPHERAL INTERFACE

This design example shows how a single 8255A in Mode 0 may be used to develop a status driven interface (no interrupts) for the Centronics 306 character printer, the Remex paper tape punch, and the Remex paper tape reader.

# 8255A To Peripheral Hardware Interface

The first step in the design is to examine the specification for the peripheral devices and identify the control and data signals which must be supported by the interface. Table III lists the signals which were chosen to be supported by the 8255A interface. All three of the devices support the standard

Table III. Peripheral Interface Signals

BUSY/DATA STROBE interface discussed previously (see Figure 10). Figure 13 is a block diagram of the interface design. The 8255A Port A is configured as a Mode 0 output port which is used to support the printer and the paper tape punch data bus. Port B is configured as a Mode 0 input port and is used to input the paper tape reader data. Three of the Port C lower bits (PC<sub>2</sub>-PC<sub>0</sub>) configured in input mode are used to input the device busy indications. Three of the Port C upper bits (PC<sub>6</sub>-PC<sub>4</sub>) configured in output mode are used to support the device strobe signals required by each device.

The drive requirements of the interface lines are a function of the peripheral interface circuitry, the length of the interface cable, and the environment in which the unit is running. In this particular design example, all output lines from the 8255A to the peripherals were buffered through a 7407 buffer/driver. The input lines from the peripherals were fed directly into the Port C and Port B inputs.

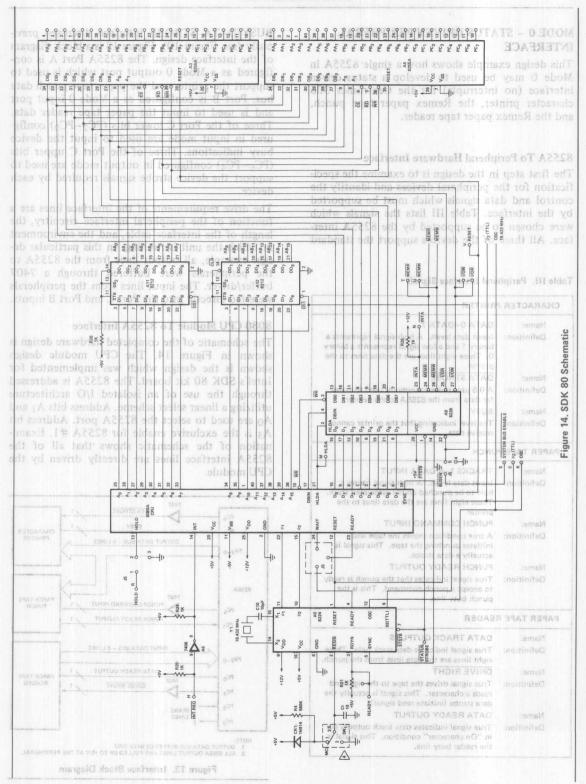

# 8080 CPU Module To 8255A Interface

The schematic of the completed hardware design is shown in Figure 14. The CPU module design shown is the design which was implemented for Intel's SDK 80 kit board. The 8255A is addressed through the use of an isolated I/O architecture utilizing a linear select scheme. Address bits A<sub>1</sub> and A<sub>0</sub> are used to select the 8255A port. Address bit A<sub>3</sub> is the exclusive enable for 8255A #1. Examination of the schematic shows that all of the 8255A interface lines are directly driven by the CPU module.

 ALL 8255A OUTPUT LINES ARE PULLED UP TO +5 V AT THE PERIPHERAL.

Figure 13. Interface Block Diagram

# Mode 0 Interface Software

An initialization routine and three device drivers (one for each peripheral device) are required to support the peripheral interface. The I/O port addresses implemented by the hardware are shown in Figure 15. The unused chip select bits are set to one so that chip select conflicts will not result if the unused bits are required by an expanded system.

The three peripheral drivers which follow all have the basic structure discussed previously. Consider the printer routine. Here the user routine places an ASCII data character in the C-register and passes control to the LPST location through a subroutine call. The printer driver interrogates the status of the printer by reading Port C. If the printer is busy, the routine will loop until the printer is idle. When the printer is ready to accept a data character, the character is placed on the Port A lines and a DATA STROBE is generated. After generating the DATA STROBE, the driver executes a subroutine return to the caller.

The DATA STROBE signals to the devices are generated through the use of the Port C bit set/reset feature. The bit set/reset control words used are shown in Figure 17.

# Summary/Conclusions

This design example discussed the basic hardware and software required to handle a simple device interface. The 8255A will easily accommodate a more complex interface design which utilizes additional interface lines supported by the peripheral.

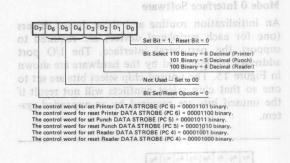

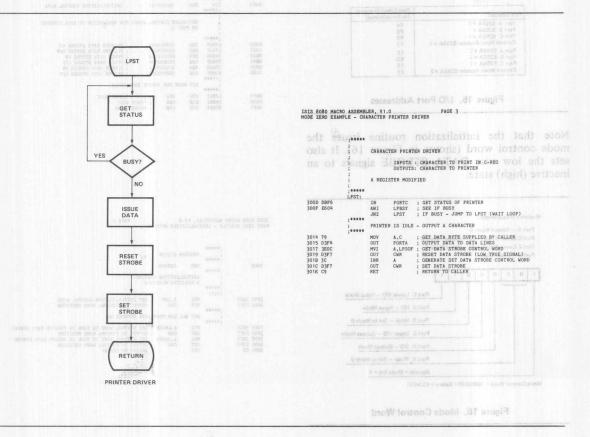

Figure 17. Bit Set/Reset Control Words

For instance, one of the spare Port C output lines may be used to control the punch direction. Support of this additional feature would require minor modification of the device driver so that the punch direction line could be specified by the user routine.

Through consideration of this example, the use of the 8255A in Mode 0 should become evident.

READER DRIVER

ONS ANATOR INTERIOR DESCRIPCE IN THE PREVIOUS ous example required the software driver to poll the device status for completion. An alternate approach is to construct the device interface such that an interrupt is used to signal the completion of the operation. When an interrupt driven interface is utilized, the time that was dedicated to polling can be used to perform other functions and the effective processor through-put is increased. This example demonstrates how an 8255A configured in Mode 1 may be used to develop an interrupt driven interface for the Centronics 306 character printer.

# CPU Module To 8255A Interface

The 8080 bus interface implemented for this example is the same as the Mode 0 example with the addition of interrupt support. Interrupt support is implemented through the use of a special feature of the 8228 System Controller. If only one interrupt vector is required (such as in small systems), the 8228 can automatically assert an RST 7 instruction onto the data bus at the proper time. This option is selected by connecting the INTA output of the 8228 to the +12-volt supply through a 1K ohm series resistor.

The Mode 1 interrupt support logic of the 8255A provides an interrupt request line for each port. The 8255A interrupt request line (INTRA) must be connected to the INT line of the 8080. A 10K ohm pullup resistor is used to insure that the VIH requirements of the 8080 are met.

# 8255A To Peripheral Interface

The interrupt driven configuration control signal interface to the printer is different than the status driven interface. Instead of a BUSY/DATA STROBE interface, a DATA STROBE/ACK interface is supported. The ACK signal notifies the 8255A that a character transferred to the printer by a DATA STROBE has been accepted. After an ACK is issued the printer is considered idle. The block diagram shown in Figure 18 displays the interface signals used.

The Mode 1 interrupt driven peripheral support signals used are:

PA<sub>7</sub>-PA<sub>0</sub> - Output Data

Used to support the printer data port.

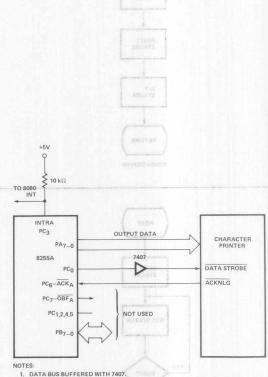

OBF

- Output Buffer Full

This line goes low when data is placed in the output buffer. The OBF signal may be used as a data partie input. The Controlles 200 requires a pulsed DATA STROBE signal. This signal is supported by Port C bit 0.

ACK ACKnowledge

> This line is used to signal the 8255A that the device has accepted the data. This line is supported by the printer ACKNLG signal.

ALL 8255A OUTPUT LINES ARE PULLED UP TO +5 V AT THE PERIPHERAL

Figure 18. Interface Block Diagram

# Mode 1 Software Driver

The software driver implemented for this example utilizes the typical interrupt driven software structure outlined previously. The initialization routine issues the mode control word (shown in Figure 19) to the 8255A after reset of the device. The initialization routine also places a jump to the interrupt service routine in the interrupt location for RST 7. The command processor is started by the user routine through a subroutine call to PSTRT, with the address of the control block in the D and E registers (the control block format is shown in Table IV). The command processor insures that an I/O operation is not already in progress, starts the I/O, enables interrupts, and returns to the caller so that other processing may proceed.

After a character is placed in the output buffer, the DATA STROBE signal is generated through the use of the Port C bit set/reset feature. When the ACK is generated by the printer, the buffer full indication is cleared and the 8255A generates an interrupt. If interrupts are enabled, the interrupt request is serviced by the 8080 CPU through disabling processor interrupts and then executing the instruction at location 38 hexadecimal in program memory. The interrupt service routine saves the processor state and polls the 8255A to determine the source of the interrupt. Once the interrupting device is located, the control block is used to locate the next data character for transfer to the 8255A output buffer. After the entire buffer has been printed, the interrupt service routine passes control to the user-supplied completion routine. Before returning from the interrupt, the state of the processor is restored.

## NOTES:

- 1. An opcode field is not required because WRITE is the only operation performed.
- 2. The control block must reside above location FF Hex.

There are a number of error conditions which may occur, such as an interrupt from a device which does not have a control block in progress, or an interrupt when polling establishes that no device requires service. Neither of these errors should occur, but if they do, the driver should perform in a consistent fashion. The recovery routines implemented to handle error conditions are determined by the particular applications environment.

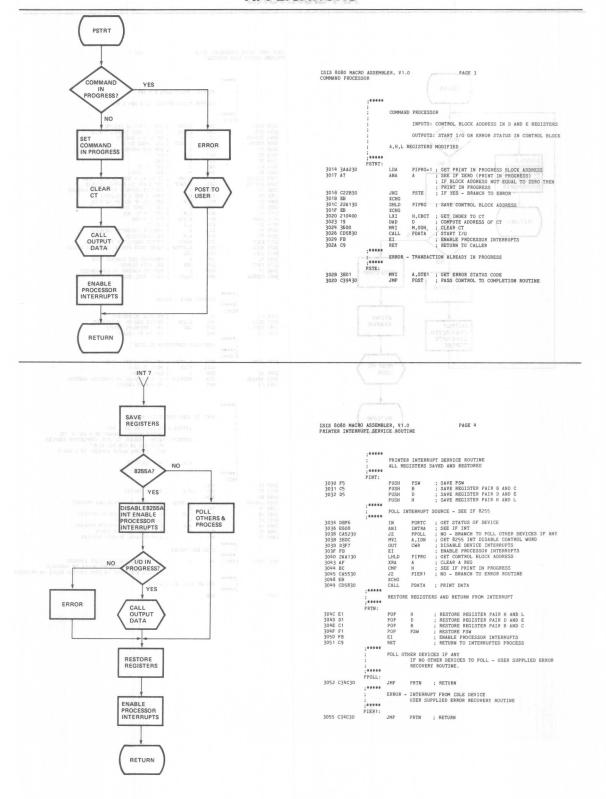

# Summary/Conclusions

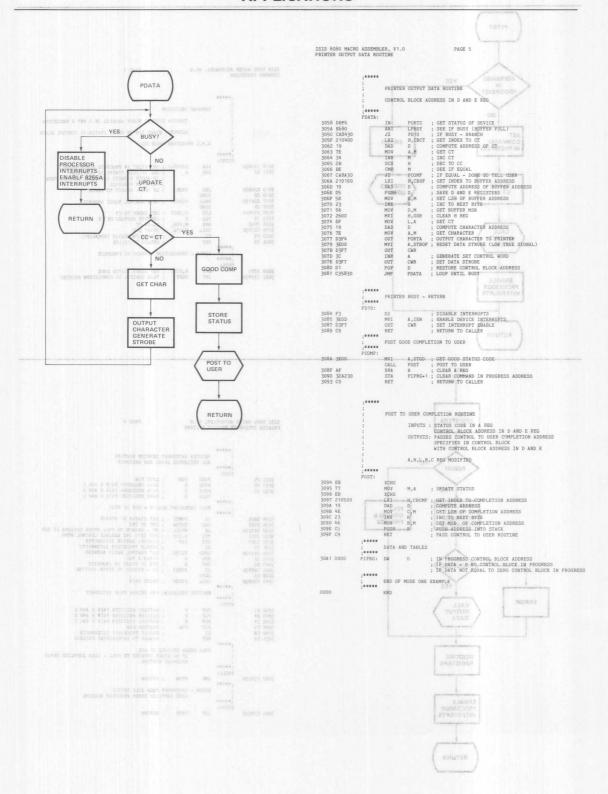

When utilized in a small system design, the 8255A interrupt support logic provides all of the capabilities required to implement an interrupt driven hardware interface without the use of external logic. In larger system designs, the designer may chose to use additional hardware to determine the source of interrupt requests without software polling. The software design required by an interrupt driven system is inherently more complex than the status driven interface. If an interrupt driven system is required the added complexity is a small price to pay for a significant increase in system through-put.

# MODE 2 - 8080 TO 8080 INTERFACE

Due to the drastic reduction of hardware costs, system designs which utilize multiple CPU Modules are becoming more common. An 8080 may be configured as a master CPU and used to control multiple 8080 slave modules which act as intelligent I/O controllers. When multiple CPUs are utilized, a method of processor intercommunication must be supported. Figure 20 is a block diagram of one method of implementing a master/slave interface through the use of the 8255A Mode 2 bidirectional bus.

# Hardware Discussion

Two complete 8080 systems are required for this example. Intel's SBC 80/10 OEM board is used as the master CPU module and Intel's SDK 80 board is used as the slave CPU. The SBC 80/10 supports an 8255A which is configured in Mode 2. The 8255A is selected through the use of a decoded select scheme. Through the use of the 8228 RST 7 interrupt feature, a simple interrupt structure is supported. The SDK 80 is configured without interrupts for this example. The external logic required for this example is associated with the slave CPU. Simple logic is implemented which allows the slave CPU to generate the ACK and STB signals required to READ from and WRITE to the 8255A-bidirectional bus with a single I/O instruction.

The system shown in Figure 20 utilizes SSI logic to read the 8255A IBF and OBF signals. If two spare 8255A input lines are available they could be used to input the IBF and OBF signals and eliminate the SSI logic.

# Software Discussion

Two sets of software are required to support the processor to processor interface. The master resident software which follows conforms to the simple interrupt driven software structure outlined previously. The initialization routine issues the Mode 2 control word to the 8255A after device reset. The command processor accepts READ/WRITE control blocks which provide a simple user interface for transferring data to/from the slave CPU. The master software is capable of processing both a read and a write control block simultaneously. The slave resident software shown at the end of this example utilizes the status driven approach.

# Summary/Conclusions

It is important to note that this design may be expanded to include more slave CPUs by simply adding another 8255A to the master module for each slave. The software drivers discussed address only the passing of data between the two processors. Specific applications generally dictate a software protocol be implemented for information transfer.

# 1. INTRODUCTION

The purpose of this application note is to provide the reader with the design concepts and factual tools needed to integrate Intel peripherals and microprocessors into a low cost raster scan CRT terminal. A previously published application note, AP-32, presented one possible solution to the CRT design question. This application note expands upon the theme established in AP-32 and demonstrates how to design a functional CRT terminal while keeping the parts count to a minimum.

For convenience, this application note is divided into seven general sections:

- 1. Introduction
- 2. CRT Basics
- 3. 8275 Description
- 4. Design Background
- 5. Circuit Description
- 6. Software Description
- 7. Appendix

There is no question that microprocessors and LSI peripherals have had a significant role in the evolution of CRT terminals. Microprocessors have allowed design engineers to incorporate an abundance of sophisticated features into terminals that were previously mere slaves to a larger processor. To complement microprocessors, LSI peripherals have reduced component count in many support areas. A typical LSI peripheral easily replaces between 30 and 70 SSI and MSI packages, and offers features and flexibility that are usually not available in most hardware designs. In addition to replacing a whole circuit board of random logic, LSI circuits also reduce the cost and increase the reliability of design. Fewer interconnects increases mechanical reliability and fewer parts decreases the power consumption and hence, the overall reliability of the design. The reduction of components also yields a circuit that is easier to debug during the actual manufacturing phase of a product.

Until the era of advanced LSI circuitry, a typical CRT terminal consisted of 80 to 200 or more SSI and MSI packages. The first microprocessors and peripherals dropped this component count to between 30 and 50 packages. This application note describes a CRT terminal that uses 20 packages.

# 2. CRT BASICS

The raster scan display gets its name from the fact that the image displayed on the CRT is built up by generating a series of lines (raster) across the face of the CRT. Usually, the beam starts in the upper left hand corner of the display and simultaneously moves left to right and top to bottom to put a series

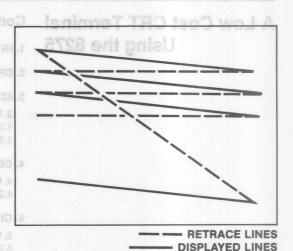

Figure 2-1. Raster Scan

of zig-zag lines on the screen (Fig. 2.1). Two simultaneously operating independent circuits control the vertical and horizontal movement of the beam.

As the electron beam moves across the face of the CRT, a third circuit controls the current flowing in the beam. By varying the current in the electron beam the image on the CRT can be made to be as bright or as dark as the user desires. This allows any desired pattern to be displayed.

When the beam reaches the end of a line, it is brought back to the beginning of the next line at a rate that is much faster than was used to generate the line. This action is referred to as "retrace". During the retrace period the electron beam is usually shut off so that it doesn't appear on the screen.

As the electron beam is moving across the screen horizontally, it is also moving downward. Because of this, each successive line starts slightly below the previous line. When the beam finally reaches the bottom right hand corner of the screen, it retraces vertically back to the top left hand corner. The time it takes for the beam to move from the top of the screen to the bottom and back again to the top is usually referred to as a "frame". In the United States, commercial television broadcast use 15,750 Hz as the horizontal sweep frequency (63.5 microseconds per horizontal line) and 60 Hz as the vertical sweep frequency or "frame" (16.67 milliseconds per vertical frame).

Although, the 60 Hz vertical frame and the 15,750 Hz horizontal line are the standards used by commercial broadcasts, they are by no means the only frequency at which CRT's can operate. In fact, many CRT displays use a horizontal scan that is around 18 KHz to 22 KHz and some even exceed 30 KHz. As the

horizontal frequency increases, the number of horizontal lines per frame increases. Hence, the resolution on the vertical axis increases. This increased resolution is needed on high density graphic displays and on special text editing terminals that display many lines of text on the CRT.

Although many CRT's operate at non-standard horizontal frequencies, very few operate at vertical frequencies other than 60 Hz. If a vertical frequency other than 60 Hz is chosen, any external or internal magnetic or electrical variations at 60 Hz will modulate the electron beam and the image on the screen will be unstable. Since, in the United States, the power line frequency happens to be 60 Hz, there is a good chance for 60 Hz interference to exist. Transformers can cause 60 Hz magnetic fields and power supply ripple can cause 60 Hz electrical variations. To overcome this, special shielding and power supply regulation must be employed. In this design, we will assume a standard frame rate of 60 Hz and a standard line rate of 15,750 Hz.

By dividing the 63.5 microsecond horizontal line rate into the 16.67 millisecond vertical rate, it is found that there are 262.5 horizontal lines per vertical frame. At first, the half line may seem a bit odd, but actually it allows the resolution on the CRT to be effectively doubled. This is done by inserting a second set of horizontal lines between the first set (interlacing). In an interlaced system the line sets are not generated simultaneously. In a 60 Hz system, first all of the even-numbered lines are scanned: 0, 2, 4,...524. Then all the odd-numbered lines: 1, 3, 5,... 525. Each set of lines usually contains different data (Fig. 2.2).

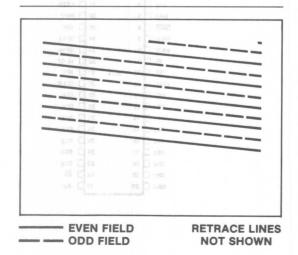

Figure 2-2. Interlaced Scan

Although interlacing provides greater resolution, it also has some distinct disadvantages. First of all, the circuitry needed to generate the extra half horizontal line per frame is quite complex when compared to a noninterlaced design, which requires an integer number of horizontal lines per frame. Next, the overall vertical refresh rate is half that of a noninterlaced display. As a result, flicker may result when the CRT uses high speed phosphors. To keep things as simple as possible, this design uses the noninterlaced approach.

The first thing any CRT controller must do is generate pulses that define the horizontal line timing and the vertical frame timing. This is usually done by dividing a crystal reference source by some appropriate numbers. On most raster scan CRT's the horizontal frequency is very forgiving and can vary by around 500 Hz or so and produce no ill effects. This means that the CRT itself can track a horizontal frequency between 15250 Hz and 16250 Hz, or in other words, there can be 256 to 270 horizontal lines per vertical frame. But, as mentioned earlier, the vertical frequency should be 60 Hz to insure stability.

The characters that are viewed on the screen are formed by a series of dots that are shifted out of the controller while the electron beam moves across the face of the CRT. The circuits that create this timing are referred to as the dot clock and character clock. The character clock is equal to the dot clock divided by the number of dots used to form a character along the horizontal axis and the dot clock is calculated by the following equation:

DOT CLOCK (Hz) = (N + R) \* D \* L \* Fwhere N is the number of displayed characters per row,

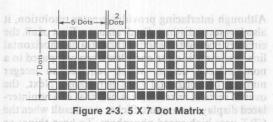

R is the number of retrace character time increments,

D is the number of dots per character,

L is the number of horizontal lines per frame and F is the frame rate in Hz.

In this design N = 80, R = 20, D = 7, L = 270, and F = 60 Hz. If the numbers are plugged in, the dot clock is found to be 11.34 MHz.

The retrace number, R, may vary from system to system because it is used to establish the margins on the left and right hand sides of the CRT. In this particular design R=20 was empirically found it be optimum. The number of dots per character may vary depending on the character generator used and the number of dot clocks the designer wants to place between characters. This design uses a 5 X 7 dot matrix and allows 2 dot clock periods between characters (see Fig. 2.3); since 5+2 equals 7, we find that D=7.

The number of lines per frame can be determined by The first thing any CRT:noitaups gniwollof add

where. H is the number of horizontal lines per character, of source source at the character, of source source or the character, of source source or the character, or source or the character or the characte

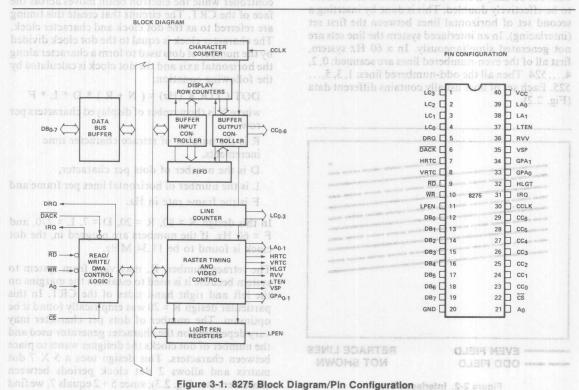

Z is the number of character lines per frame and V is the number of horizontal lines during vertical retrace. In this design, a 5 X 7 dot matrix is to be placed on a 7 X 10 field, so H = 10. Also, 25 lines are to be displayed, so Z = 25. As mentioned before, V = 20. When the numbers are plugged into the equation, L is found to be equal to 270 lines per frame.

The designer should be cautioned that these numbers

are interrelated and that to guarantee proper operation on a standard raster scan CRT, L should be between 256 and 270. If L does not lie within these bounds the horizontal circuits of the CRT may not be able to lock onto the driving signal and the image will roll horizontally. The chosen L of 270 yields a horizontal frequency of 16,200 KHz on a 60 Hz frame and this number is within the 500 Hz tolerance mentioned earlier.

The V number is chosen to match the CRT in much the same manner as the R number mentioned earlier. When the electron beam reaches the bottom right corner of the screen it must retrace vertically to the top left corner. This retrace action requires time, usually between 900-1200 microseconds. To allow for this, enough horizontal sync times must be inserted during vertical retrace. Twenty horizontal sync times at 61.5 microseconds yield a total of 1234.5 microseconds, which is enough time to allow the beam to return to the top of the screen.

The choices of H and Z largely relate to system design preference. As H increases, the character size along the vertical axis increases. Z is simply the number of lines of characters that are displayed and this, of course, is entirely a system design option.

# 3. 8275 DESCRIPTION

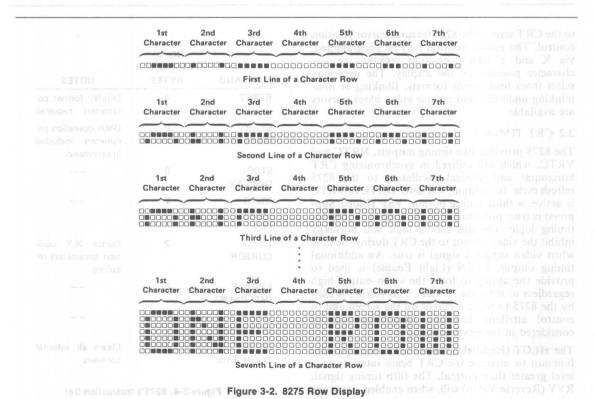

A block diagram and pin configuration of the 8275 are shown in Fig. 3.1. The following is a description of the general capabilities of the 8275.

# 3.1 CRT DISPLAY REFRESHING

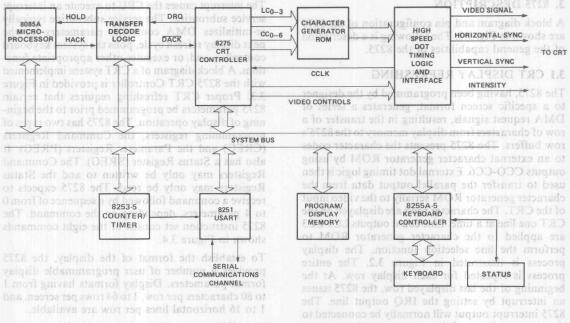

The 8275, having been programmed by the designer to a specific screen format, generates a series of DMA request signals, resulting in the transfer of a row of characters from display memory to the 8275's row buffers. The 8275 presents the character codes to an external character generator ROM by using outputs CCO-CC6. External dot timing logic is then used to transfer the parallel output data from the character generator ROM serially to the video input of the CRT. The character rows are displayed on the CRT one line at a time. Line count outputs LC0-LC3 are applied to the character generator ROM to perform the line selection function. The display process is illustrated in Figure 3.2. The entire process is repeated for each display row. At the beginning of the last displayed row, the 8275 issues an interrupt by setting the IRQ output line. The 8275 interrupt output will normally be connected to the interrupt input of the system central processor. The interrupt causes the CPU to execute an interrupt service subroutine. The service subroutine typically re-initializes DMA controller parameters for the next display refresh cycle, polls the system keyboard controller, and/or executes other appropriate functions. A block diagram of a CRT system implemented with the 8275 CRT Controller is provided in Figure 3.3. Proper CRT refreshing requires that certain 8275 parameters be programmed prior to the beginning of display operation. The 8275 has two types of programming registers, the Command Registers (CREG) and the Parameter Registers (PREG). It also has a Status Register (SREG). The Command Registers may only be written to and the Status Registers may only be read. The 8275 expects to receive a command followed by a sequence of from 0 to 4 parameters, depending on the command. The 8275 instruction set consist of the eight commands shown in Figure 3.4.

To establish the format of the display, the 8275 provides a number of user programmable display format parameters. Display formats having from 1 to 80 characters per row, 1 to 64 rows per screen, and 1 to 16 horizontal lines per row are available.

In addition to transferring characters from memory

AFN-01304A

ground mort articles and a first sense of the companies o

to the CRT screen, the 8275 features cursor position control. The cursor position may be programmed, via X and Y cursor position registers, to any character position on the display. The user may select from four cursor formats. Blinking or nonblinking underline and reverse video block cursors are available.

#### 3.2 CRT TIMING

The 8275 provides two timing outputs, HRTC and VRTC, which are utilized in synchronizing CRT horizontal and vertical oscillators to the 8275 refresh cycle. In addition, whenever HRTC or VRTC is active, a third timing output, VSP (Video Suppress) is true, providing a blinking signal to the dot timing logic. The dot timing logic will normally inhibit the video output to the CRT during the time when video suppress signal is true. An additional timing output, LTEN (Light Enable) is used to provide the ability to force the video output high regardless of the state of VSP. This feature is used by the 8275 to place a cursor on the screen and to control attribute functions. Attributes will be considered in the next section.

The HLGT (Highlight) output allows an attribute function to increase the CRT beam intensity to a level greater than normal. The fifth timing signal. RVV (Reverse Video) will, when enabled, cause the avea see stuping Figure 3-4. 8275's Instruction Set system video output to be inverted.

#### 3.3 SPECIAL FUNCTIONS

VISUAL ATTRIBUTES—Visual attributes are special codes which, when retrieved from display memory by the 8275, affect the visual characteristics of a character position or field of characters. Two types of visual attributes exist, character attributes and field attributes.

Character Attribute Codes: Character attribute codes can be used to generate graphics symbols without the use of a character generator. This is accomplished by selectively activating the Line Attribute outputs (LAO-LA1), the Video Suppression output (VSP), and the Light Enable output (LTEN). The dot timing logic uses these signals to generate the proper symbols. Character attributes can be programmed to blink or be highlighted individually. Blinking is accomplished with the Video Suppression output (VSP). Blink frequency is equal to the screen refresh frequency divided by 32. Highlighting is accomplished by activating the Highlight output (HGLT). Character attributes were designed to produce the graphic symbols shown in Figure 3.5.

Field Attribute Codes: The field attributes are control codes which affect the visual characteristics for a field of characters, starting at the character following the field attribute code up to, and including, the character which precedes the next field attribute code, or up to the end of the frame.

There are six field attributes:

 Blink — Characters following the code are caused to blink by activating the Video Suppression output (VSP). The blink frequency is equal to the screen refresh frequency divided by 32.

- 2. Highlight Characters following the code are caused to be highlighted by activating the Highlight output (HGLT).
- 3. Reverse Video Characters following the code are caused to appear in reverse video format by activating the Reverse Video output (RVV).
- 4. Underline Characters following the code are caused to be underlined by activating the Light Enable output (LTEN).
- General Purpose There are two additional 8275 outputs which act as general purpose, independently programmable field attributes. These attributes may be used to select colors or perform other desired control functions.

The 8275 can be programmed to provide visible or invisible field attribute characters as shown in Figure 3.6. If the 8275 is programmed in the visible field attribute mode, all field attributes will occupy a position on the screen. They will appear as blanks caused by activation of the Video Suppression output (VSP). The chosen visual attributes are activated after this blanked character. If the 8275 is programmed in the invisible field attribute mode. the 8275 row buffer FIFOs are activated. The FIFOs effectively lengthen the row buffers by 16 characters. making room for up to 16 field attribute characters per display row. The FIFOs are 126 characters by 7 bits in size. When a field attribute is placed in the row buffer during DMA, the buffer input controller recognizes it and places the next character in the proper FIFO. When a field attribute is placed in the buffer output controller during display, it causes the controller to immediately put a character from the FIFO on the Character Code outputs (CCO-6). The chosen attributes are also activated.

switch enables the light sensor. When the raster sweep coincides with the light sensor position on the display, the light pen output is input and the row and character position coordinates are stored in two 8275 internal registers. These registers can be read by the microprocessor. The state of seasons of the of the seasons 
SPECIAL CODES — Four special codes may be used to help reduce memory, software, or DMA overhead. These codes are placed in character positions in display memory, a starting wor on H

- 1. End Of Row Code Activates VSP. VSP remains active until the end of the line is reached. While VSP is active, the screen is blanked.
- 2. End Of Row-Stop DMA Code Causes the DMA Control Logic to stop DMA for the rest of the row when it is written into the row buffer. It affects the display in the same way as the End of Row Code.
- 3. End Of Screen Code Activates VSP. VSP remains active until the end of the frame is reached.
- 4. End Of Screen-Stop DMA Code Causes the DMA Control Logic to stop DMA for the rest of the frame when it is written into the row buffer. It affects the display in the same way as the End of Screen Code. THO THE STATE OF THE

PROGRAMMABLE DMA BURST CONTROL — The 8275 can be programmed to request single-byte DMA transfers of DMA burst transfers of 2, 4, or 8 characters per burst. The interval between bursts is also programmable. This allows the user to tailor the DMA overhead to fit the system needs.

#### 4. DESIGN BACKGROUND

#### 4.1 DESIGN PHILOSOPHY

Since the cost of any CRT system is somewhat proportional to parts count, arriving at a minimum part count solution without sacrificing performance has been the motivating force throughout this design effort. To successfully design a CRT terminal and keep the parts count to a minimum, a few things became immediately apparent.

- 1. An 8085 should be used.
- 2. Address and data buffering should be eliminated.
- 3. Multi-port memory should be eliminated.
- 4. DMA should be eliminated.

Decision 1 is obvious, the 8085's on-board clock generator, bus controller and vectored interrupts greatly reduce the overall part count considerably.

APPLICATIONS lines is kept to a minimum, both the data and address buffers can be eliminated. This easily saves three to eight packages and reduces the power consumption of the design. Both decisions 3 and 4 require a basic understanding of current CRT design concepts.

> In any CRT design, extreme time conflicts are created because all essential elements require access to the bus. The CPU needs to access the memory to control the system and to handle the incoming characters, but, at the same time, the CRT controller needs to access the memory to keep the raster scan display refreshed. To resolve this conflict two common techniques are employed, page buffering and line buffering.

> In the page buffering approach the entire screen memory is isolated from the rest of the system. This isolation is usually accomplished with three-state buffers or two line to one line multiplexers. Of course, whenever a character needs to be manipulated the CPU must gain access to the buffered memory and, again, possible contention between the CPU and the CRT controller results. This contention is usually resolved in one of two ways, (1) the CPU is always given priority, or; (2) the CPU is allowed to access the buffered memory only during horizontal and vertical retrace times.

> Approach 1 is the easiest to implement from a hardware point of view, but if the CPU always has priority the display may temporarily blink or "flicker" while the CPU accesses the display memory. This, of course, occurs because when the CPU accesses the display memory the CRT controller is not able to retrieve a character, so the display must be blanked during this time. Aesethically, this "flickering" is not desirable, so approach 2 is often used.

> The second approach eliminates the display flickering encountered in the previously mentioned technique, but additional hardware is required. Usually the vertical and horizontal blank signals are gated with the buffered memory select lines and this line is used to control the CPU's ready line. So, if the CPU wants to use the buffered memory, its ready line is asserted until horizontal or vertical retrace times. This, of course, will impact the CPU's overall through put.

> Both page buffered approaches require a significant amount of additional hardware and for the most part are not well suited for a minimum parts count type of terminal. This guides us to the line buffered approach. This approach eliminates the separate buffered memory for the display, but, at the same time, introduces a few new problems that must be solved.

Figure 4-2. Routine To Load 8275's Row Buffers

In the line buffered approach both the CPU and the CRT controller share the same memory. Every time the CRT controller needs a new character or line of data, normal processing activity is halted and the CRT controller accesses memory and displays the data. Just how the CRT controller needs to acquire the display data greatly affects the performance of the overall system. Whether the CRT controller needs to gain access to the main memory to acquire a single character or a complete line of data depends on the presence or absence of a separate line or row buffer.

If no row buffer is present the CRT controller must go to the main memory to fetch every character. This of course, is not a very efficient approach because the processor will be forced to relinquish the bus 70% to 80% of the time. So much processor inactivity greatly affects the overall system performance. In fact terminals that use this approach are typically limited to around 1200 to 2400 baud on their serial communication channels. This low baud rate is in general not acceptable, hence this approach was not chosen.

If a separate row buffer is employed the CRT controller only has to access the memory once for each displayed character per line. This forces the processor to relinquish the bus only about 20% to 35% of the time and a full 4800 to 9600 baud can be achieved. Figure 4.1 illustrates these different techniques.

The 8275 CRT controller is ideal for implementing the row buffer approach because the row buffer is contained on the device itself. In fact, the 8275 contains two 80-byte row buffers. The presence of two row buffers allow one buffer to be filled while the other buffer is displaying the data. This dual row buffer approach enhances CPU performance even further.

## 4.2 USING THE 8275 WITHOUT DMA

Until now the process of filling the row buffer has only been alluded to. In reality, a DMA technique is usually used. This approach was demonstrated in AP-32 where an 8257 DMA controller was mated to an 8275 CRT controller. In order to minimize component count, this design eliminates the DMA controller and its associated circuitry while replacing them with a special interrupt-driven transfer.

The only real concern with using the 8275 in an interrupt-driven transfer mode is speed. Eighty characters must be loaded into the 8275 every 617 microseconds and the processor must also have time to perform all the other tasks that are required. To minimize the overhead associated with loading the characters into the 8275 a special technique was employed. This technique involves setting a special

transfer bit and executing a string of POP instructions. The string of POP instructions is used to rapidly move the data from the memory into the 8275. Figure 4.2 shows the basic software structure.

In this design the 8085's SOD line was used as the special transfer bit. In order to perform the transfer properly this special bit must do two things: (1) turn processor reads into DACK plus WR for the 8275 and (2) mask processor fetch cycles from the 8275, so that a fetch cycle does not write into the 8275. Conventional logic could have been used to implement this special function, but in this design a small bipolar programmable read only memory was used. Figure 4.3 shows a basic version of the hardware.

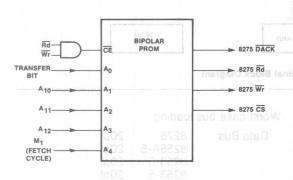

Figure 4-3. Simplified Version of Hardware Decoder

At first, it may seem strange that we are supplying a DACK when no DMA controller exist in the system. But the reader should be aware that all Intel peripheral devices that have DMA lines actually use DACK as a chip select for the data. So, when you want to write a command or read status you assert CS and WR or RD, but when you want to read or write data you assert DACK and RD or WR. The peripheral device doesn't "know" if a DMA controller is in the circuit or not. In passing, it should be mentioned that DACK and CS should not be asserted on the same device at the same time, since this combination yields an undefined result.

This POP technique actually compares quite favorably in terms of time to the DMA technique. One POP instruction transfers two bytes of data to the 8275 and takes 10 CPU clock cycles to execute, for a net transfer rate of one byte every five clock cycles. The DMA controller takes four clock cycles to transfer one byte but, some time is lost in synchronization. So the difference between the two techniques is one clock cycle per byte maximum. If we compare the overall speed of the 8085 to the

speed of the 8080 used in AP-32, we find that at 3 MHz we can transfer one byte every 1.67 microseconds using the 8085 and POP technique vs. 2 microseconds per byte for the 2 MHz 8080 using DMA.

#### 5. CIRCUIT DESCRIPTION

#### 5.1 SCOPE OF THE PROJECT

A fully functional, microprocessor-based CRT terminal was designed and constructed using the 8275 CRT controller and the 8085 as the controlling element. The terminal had many of the functions found in existing commercial low-cost terminals and more sophisticated features could easily be added with a modest amount of additional software. In order to minimize component count LSI devices were used whenever possible and software was used to replace hardware.

#### 5.2 SYSTEM TARGET SPECIFICATIONS

The design specifications for the CRT terminal were as follows:

#### Display Format

- 80 characters per display row
- 25 display rows a mammand a HOZA 30 .

# \* ASCH control characters

- 5 X 7 dot matrix character contained within a 7 X 10 matrix MOSSE NOTE TO THE PROPERTY OF T
- First and seventh columns blanked \uniquid
- Blinking underline cursor

#### Special Characters Recognized All All 0000

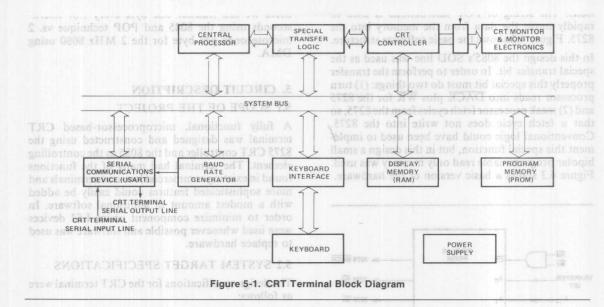

- Control characters
- Line feed
- Carriage Return
- Backspace NA beboone and bushnats vnA
- · Form feed

#### Escape Sequences Recognized

#### **5.3 HARDWARE DISCRIPTION**

A block diagram of the CRT terminal is shown in Figure 5.1. The diagram shows only the essential system features. A detailed schematic of the CRT is contained in the Appendix. The terminal was constructed on a simple 6" by 6" wire wrap board. Because of the minimum bus loading no buffering of any kind was needed (see Figure 5.2).

The "heart" of the CRT terminal is the 8085 microprocessor. The 8085 initializes all devices in the system, loads the CRT controller, scans the keyboard, assembles the characters to be trans-

| Worst case bus   | loading:                  |                      |                                   |

Figure 5-2. Bus Loading

mitted, decodes the incoming characters and determines where the character is to be placed on the screen. Clearly, the processor is quite busy.

A standard list of LSI peripheral devices surround the 8085. The 8251A is used as the serial communication link, the 8255A-5 is used to scan the keyboard and read the system variables through a set of

switches, and the 8253 is used as a baud rate generator and as a "horizontal pulse extender" for the 8275

The 8275 is used as the CRT controller in the system, and a 2716 is used as the character generator. To handle the high speed portion of the terminal the 8275 is surrounded by a small handful of TTL. The program memory is contained in one 2716 EPROM and the data and screen memory use four 2114-type RAMs.

All devices in this system are memory mapped. A bipolar PROM is used to decode all of the addresses for the RAM, ROM, 8275, and 8253. As mentioned earlier, the bipolar prom also turns READs into DACK's and WR's for the 8275. The 8255 and 8253 are decoded by a simple address line chip select method. The total package count for the system is 20, not including the serial line drivers. If this same terminal were designed using the MCS-85 family of integrated circuits, additional part savings could have been realized. The four 2114's could have been replaced by two 8185's and the 8255 and the 2716 program PROM could have been replaced by one 8755. Additionally, since both the 8185 and the 2716 have address latches no 8212 would be needed so the total parts count could be reduced by three or four packages.

#### 5.4 SYSTEM OPERATION

The 8085 CPU initializes each peripheral to the appropiate mode of operation following system reset. After initialization, the 8085 continually polls the 8251A to see if a character has been sent to the terminal. When a character has been received, the 8085 decodes the character and takes appropriate action. While the 8085 is executing the above "foreground" programs, it is being interrupted once every 617 microseconds by the 8275. This "background" program is used to load the row buffers on the 8275. The 8085 is also interrupted once every frame time, or 16.67 ms, to read the keyboard and the status of the 8275.

As discussed earlier, a special POP technique was used to rapidly move the contents of the display RAM into the 8275's row buffers. The characters are then synchronously transferred to the character code outputs CC0-CC6, connected to the character generator address lines A3-A9 (Figure 5.3). Line count outputs LC0-LC2 from the 8275 are applied to the character generator address lines, A0-A2. The 8275 displays character rows one line at a time. The line count outputs are used to determine which line of the character selected by A3-A8 will be displayed. Following the transfer of the first line to the dot timing logic, the line count is incremented and the second line of the character row is selected. This

process continues until the last line of the row is transferred to the dot timing logic.

The dot timing logic latches the output of the character generator ROM into a parallel in, serial out synchronous shift register. This shift register is clocked at the dot clock rate (11.34 MHz) and its output constitutes the video input to the CRT.

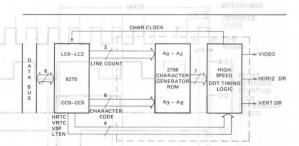

Figure 5-3 Character Generator/Dot Timing Logic Block Diagram

Table 5-1

| PARAMETER                          | RANGE                  |

| Horizontal Repetition Rate         | 15,750 ±500 pps        |

#### 5.5 SYSTEM TIMING

Before any specific timing can be calculated it is necessary to determine what constraints the chosen CRT places on the overall timing. The requirements for the Ball Bros. TV-12 monitor are shown in Table 5.1. The data from Table 5.1, the 8275 specifications, and the system target specifications are all that is needed to calculate the system's timing.

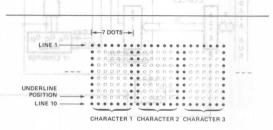

Figure 5-4. Row Format

First, let's select and "match" a few numbers. From our target specifications, we see that each character is displayed on a 7 X 10 field, and is formed by a 5 X 7 dot matrix (Figure 5.4). The 8275 allows the vertical retrace time to be only an integer multiple of

the horizontal character line. This means that the total number of horizontal lines in a frame equals 10 times the number of character lines plus the vertical retrace time, which is programmed to be either 1, 2, 3, or 4 character lines. Twenty-five display lines

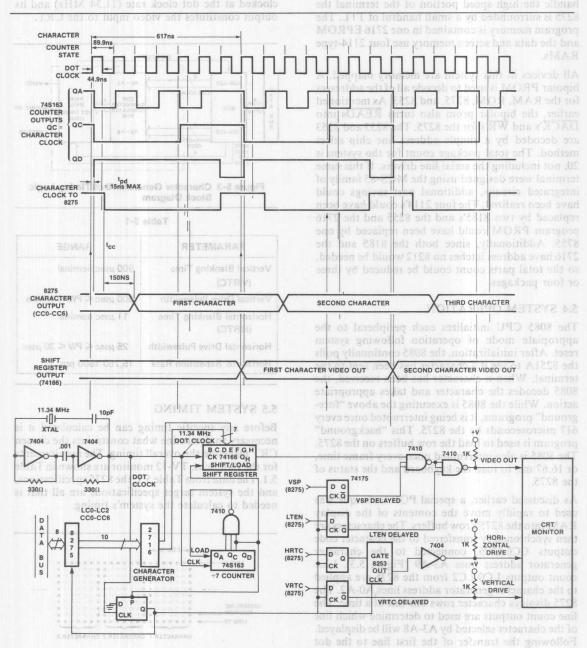

figure 5-5. Dot Timing Logic streaments is incremente signal gnimit

require 250 horizontal lines. So, if we wish to have a horizontal frequency in the neighborhood of 15,750 Hz we must choose either one or two character lines for vertical retrace. To allow for a little more margin at the top and bottom of the screen, two character lines were chosen for vertical retrace. This choice yields a net 250 + 20 = 270 horizontal lines per frame. So, assuming a 60 Hz frame:

60 Hz \* 270 = 16,200 Hz (horizontal frequency)

This value falls within our target specification of 15,750 Hz with a 500 Hz variation and also assures timing compatibility with the Ball monitor since, 20 horizontal sync times yield a vertical retract time of:

61.7 microseconds X 20 horizontal sync times = 1.2345 milliseconds

This number meets the nominal VRTC and vertical drive pulse width time for the Ball monitor. A horizontal frequency of 16,200 Hz implies a 1/16,200 = 61.73 microsecond period.

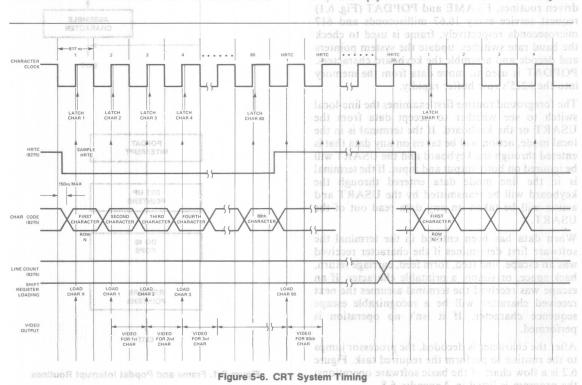

It is now known that the terminal is using 250 horizontal lines to display data and 20 horizontal lines to allow for vertical retrace and that the horizontal frequency is 16,200 Hz. The next thing that needs to be determined is how much time must

be allowed for horizontal retrace. Unfortunately, this number depends almost entirely on the monitor used. Usually, this number lies somewhere between 15 and 30 percent of the total horizontal line time, which in this case is 1/16,200 Hz or 61.73 microseconds. Since in most designs a fixed number of characters can be displayed on a horizontal line, it is often useful to express retrace as a given number of character times. In this design, 80 characters can be displayed on a horizontal line and it was empirically found that allowing 20 horizontal character times for retrace gave the best results. So, in reality, there are 100 character times in every given horizontal line, 80 are used to display characters and 20 are used to allow for retrace. It should be noted that if too many character times are used for retrace, less time will be left to display the characters and the display will not "fill out" the screen. Conversely, if not enough character times are allowed for retrace, the display may "run off" the screen.

One hundred character times per complete horizontal line means that each character requires #37242.

61.73 microseconds /100 character times = 617.3 nanoseconds.

If we multiply the 20 horizontal retrace times by the

2-453

microseconds was all addition and where

This value falls short of the 25 to 30 microseconds required by the horizontal drive of the Ball monitor. To correct for this, an 8253 was programmed in the one-shot mode and was used to extend the horizontal drive pulsewidth.

Now that the 617.3 nanosecond character clock period is known, the dot clock is easy to calculate. Since each character is formed by placing 7 dots along the horizontal.

DOT CLOCK PERIOD = 617.3 ns (CHARACTER CLK PERIOD)/ 7 DOTS DOT CLOCK PERIOD = 88.183 nanoseconds DOT CLOCK FREQUENCY = 1/PERIOD = 11.34 MHz

Figures 5.5 and 5.6 illustrate the basic dot timing and the CRT system timing, respectively.

#### 6. SYSTEM SOFTWARE do does ladt agesta sail

#### 6.1 SOFTWARE OVERVIEW

As mentioned earlier the software is structured on a "foreground-background" basis. Two interrupt-driven routines, FRAME and POPDAT (Fig. 6.1) request service every 16.67 milliseconds and 617 microseconds respectively, frame is used to check the baud rate switches, update the system pointers and decode and assemble the keyboard characters. POPDAT is used to move data from the memory into the 8275's row buffer rapidly.

The foreground routine first examines the line-local switch to see whether to accept data from the USART or the keyboard. If the terminal is in the local mode, action will be taken on any data that is entered through the keyboard and the USART will be ignored on both output and input. If the terminal is in the line mode data entered through the keyboard will be transmitted by the USART and action will be taken on any data read out of the USART.

When data has been entered in the terminal the software first determines if the character received was an escape, line feed, form feed, carriage return, back space, or simply a printable character. If an escape was received the terminal assumes the next received character will be a recognizable escape sequence character. If it isn't no operation is performed.

After the character is decoded, the processor jumps to the routine to perform the required task. Figure 6.2 is a flow chart of the basic software operations; the program is listed in Appendix 6.8.

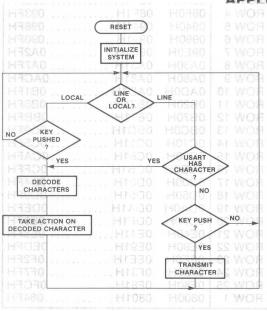

Figure 6-2. Basic Terminal Software

#### 6.2 SYSTEM MEMORY ORGANIZATION

The display memory organization is shown in Figure 6.3. The display begins at location 0800H in memory and ends at location 0FCFH. The 48 bytes of RAM from location 0FD0H to 0FFFH are used as system stack and temporary system storage. 2K bytes of PROM located at 0000H through 07FFH contain the systems program.

#### 6.3 MEMORY POINTERS AND SCROLLING

To calculate the location of a character on the screen, three variables must be defined. Two of these variables are the X and Y position of the cursor (CURSX, CURSY). In addition, the memory address defining the top line of the display must be known, since scrolling on the 8275 is accomplished simply by changing the pointer that loads the 8275's row buffers from memory. So, if it is desired to scroll the display up or down all that must be changed is one 16-bit memory pointer. This pointer is entered into the system by the variable TOPAD (TOP Address) and always defines the top line of the display. Figure 6.4 details screen operation during scrolling.

Figure 6-3. Screen Display After Initialization

Subroutines CALCU (Calculate) and ADX (ADd X axis) use these three variables to calculate an absolute memory address. The subroutine CALCU is used whenever a location in the screen memory must be altered.

#### 6.4 SOFTWARE TIMING

One important question that must be asked about the terminal software is, "How fast does it run". This is important because if the terminal is running at 9600 baud, it must be able to handle each received character in 1.04 milliseconds. Figure 6.5 is a flowchart of the subroutine execution times. It should be pointed out that all of the times listed are "worst case" execution times. This means that all routines assume they must do the maximum amount of data manipulation. For instance, the PUT routine assumes that the character is being placed in the last column and that a line feed must follow the placing of the character on the screen.

How fast do the routines need to execute in order to assure operation at 9600 baud? Since POPDAT interrupts occur every 617 microseconds, it is possible to receive two complete interrupt requests in every character time (1042 microseconds) at 9600

| ROW 1    | 0800H  | 0801H                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          | 084FH   | ROW 2            | 0850H 0851H089F                     |

baud. Each POPDAT interrupt executes in 211 microseconds maximum. This means that each routine must execute in:

1042 - 2 \* 211 = 620 microseconds

By adding up the times for any loop, it is clear that all routines meet this speed requirement, with the exception of ESC J. This means that if the terminal is operating at 9600 baud, at least one character time must be inserted after an ESC J sequence.

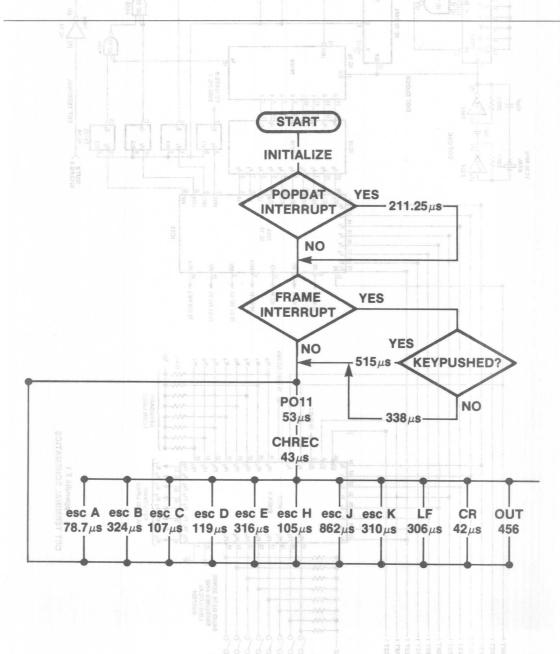

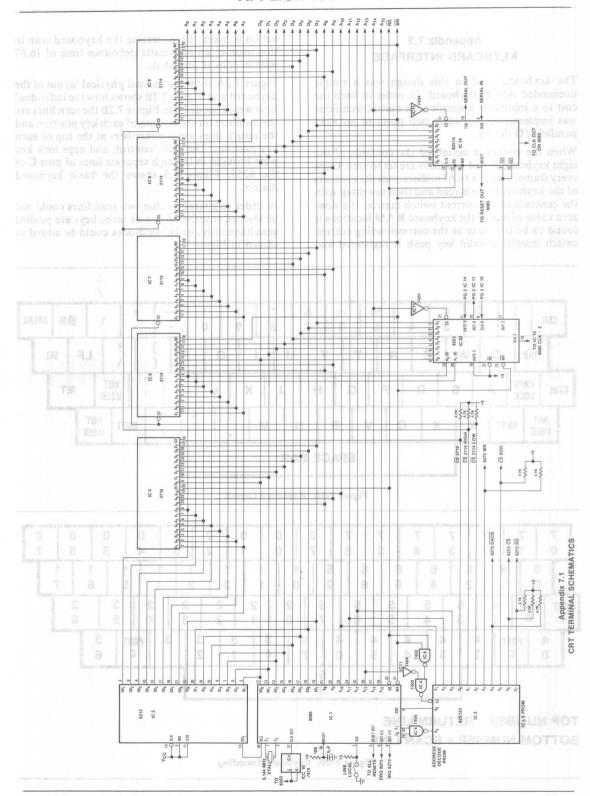

Figure 6-5. Timing Flowchart

# Appendix 7.2 KEYBOARD INTERFACE

The keyboard used in this design was a simple unencoded ASCII keyboard. In order to keep the cost to a minimum a simple scan matrix technique was implemented by using two ports of an 8255 parallel I/O device.

When the system is initialized the contents of the eight keyboard RAM locations are set to zero. Once every frame, which is 16.67 milliseconds the contents of the keyboard ram is read and then rewritten with the contents of the current switch matrix. If a non-zero value of one of the keyboard RAM locations is found to be the same as the corresponding current switch matrix, a valid key push is registered and

action is taken. By operating the keyboard scan in this manner an automatic debounce time of 16.67 milliseconds is provided.

Figure 7.2A shows the actual physical layout of the keyboard and Figure 7.2B shows how the individual keys were encoded. On Figure 7.2B the scan lines are the numbers on the bottom of each key position and the return lines are the numbers at the top of each key position. The shift, control, and caps lock key were brought in through separate lines of port C of the 8255. Figure 7.3 shows the basic keyboard matrix.

In order to guarantee that two scan lines could not be shorted together if two or more keys are pushed simultaneously, isolation diodes could be added as shown in Figure 7.4.

device was chosen simply because it is the only "by
eight" prom available in a 16 pm package. The
connection of the gram is shown in detail in Figure
7.5 and its truth table is shown in Figure 7.6. Note
that when a fetch cycle (Mijospino qui berongi sia Jud betsenge ed nas sent) of the SOD line is the only thing that
determines if memory reads will be written into the
8275s row buffers. This is done by pulling both
DACK and WRITE low on the 8275.

Also note that all of the outputs of the bipolar prom MUST BE PULLED HIGH by a resistor. This

Floure 7-4. Isolating Scan Lines With Diodes.

disabled

NOTE:

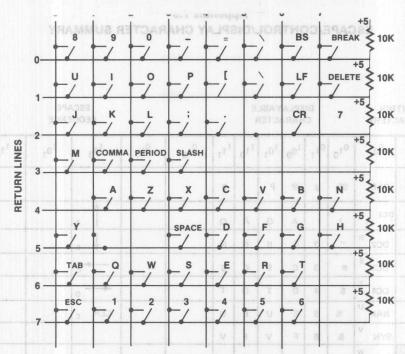

Figure 7-3. Keyboard Matrix

# Appendix 7.4 PROM DECODING

As stated earlier, all of the logic necessary to convert the 8275 into a non-DMA type of device was performed by a single small bipolar prom. Besides turning certain processor READS into DACKS and WRITES for the 8275, this 32 by 8 prom decoded addresses for the system ram, rom, as well as for the 8255 parallel I/O port.

Any bipolar prom that has a by eight configuration could function in this application. This particular device was chosen simply because it is the only "by eight" prom available in a 16 pin package. The connection of the prom is shown in detail in Figure 7.5 and its truth table is shown in Figure 7.6. Note that when a fetch cycle (M1) is not being performed, the state of the SOD line is the only thing that determines if memory reads will be written into the 8275's row buffers. This is done by pulling both DACK and WRITE low on the 8275.

Also note that all of the outputs of the bipolar prom MUST BE PULLED HIGH by a resistor. This prevents any unwanted assertions when the prom is disabled.

# 8.7 xibseqqA Appendix 7.5 9370A9AHO 30 9 CHARACTER GENERATOR

As previously mentioned, the character generator used in this terminal is a 2716 or 2758 EPROM. A 1K by 8 device is sufficient since a 128 character 5 by 7 dot matrix only requires 8K of memory. Any "standard" or custom character generator could have been used.

The three low-order line count outputs (LC0-LC2) from the 8275 are connected to the three low-order address lines of the character generator and the seven character generator outputs (CC0-CC6) are connected to A3-A9 of the character generator. The output from the character generator is loaded into a shift register and the serial output from the shift register is the video output of the terminal.

Now, let's assume that the letter "E" is to be displayed. The ASCII code for "E" is 45H. So, 45H is presented to address lines A2-A9 of the character generator. The scan lines will now count each line from zero to seven to "form" the character as shown in Fig. 7.7. This same procedure is used to form all 128 possible characters.

It should be obvious that "custom" character fonts could be made just by changing the bit patterns in the character generator PROM. For reference, Appendix 7.6 contains a HEX dump of the character generator used in this terminal.

45H = 01000101 Address to Prom = 01000101 SL2 SL1 SL0 = 228H - 22FH

Depending on state of Scan lines.

Character generator output

| Rom Address | Rom Hex | Output | Bi  | t Ou | tput* |   |
|-------------|---------|--------|-----|------|-------|---|
| 228H        | 3E      | 0      | 1 2 | 3 4  | 5 6   | 7 |
| 229H        | 02      |        | XX  | XX   | X     |   |
| 22AH        | 02      |        | X   |      |       |   |
| 22BH        | 0E      |        | X   |      |       |   |
| 22CH        | 02      |        | XX  | X    |       |   |
| 22DH        | 02      |        | X   |      |       |   |
| 22EH        | 3E      |        | X.  |      |       |   |
| 22FH 0000   | 00      |        | XX  | 20   | X     |   |
|             | FUNIT   |        |     |      |       |   |

Bits 0, 6 and 7 are not used.

Figure 7-7. Character Generation

<sup>\*</sup> note bit output is backward from convention.

# Appendix 7.6 ROTARBUBD RETHEX DUMP OF CHARACTER GENERATOR

# Appendix 7.7 COMPOSITE VIDEO

In this design, it was assumed that the monitor required a separate horizontal drive, vertical drive, and video input. However, many monitors require a composite video signal. The schematic shown in Figure 7.8 illustrates how to generate a composite video signal from the output of the 8275.

The dual one-shots are used to provide a small delay and the proper horizontal and vertical pulse to the composite video monitor. The delay introduced in the vertical and horizontal timing is used to "center" the display. VR1 and VR2 control the amount of delay. IC3 is used to mix the vertical and horizontal retrace and Q1 along with the R1, R2, and R3 mix the video and the retrace signal and provide the proper DC levels.
